**Multiple sclerosis (MS) is a chronic inflammatory demyelinating disease of the central nervous system of unknown etiology. We tested the hypothesis that MS is caused by Epstein-Barr virus (EBV) in a cohort comprising more than 10 million young adults on active duty in the US military, 955 of whom were diagnosed with MS during their period of service. Risk of MS increased 32-fold after infection with EBV but was not increased after infection with other viruses, including the similarly transmitted cytomegalovirus. Serum levels of neurofilament light chain, a biomarker of neuroaxonal degeneration, increased only after EBV seroconversion. These findings cannot be explained by any known risk factor for MS and suggest EBV as the leading cause of MS.**

## Infection with Epstein-Barr virus is the trigger for the development of multiple sclerosis

Infection with the Epstein-Barr virus (EBV) has long been postulated to trigger multiple sclerosis (MS) (1). Prior analyses demonstrated increased serum antibodies to EBV in ~99.5% of MS patients compared with ~94% of healthy individuals (2). On page 296 of this issue, Bjornevik *et al.* (3) analyzed EBV antibodies in serum from 801 individuals who developed MS among a cohort of >10 million people active in the US military over a 20-year period (1993–2013). Thirty-five of the 801 MS cases were initially EBV seronegative, and 34 became infected with EBV before the onset of MS. EBV seropositivity was nearly ubiquitous at the time of MS development, with only one of 801 MS cases being EBV seronegative at the time of MS onset. These findings provide compelling data that implicate EBV as the trigger for the development of MS.

How does a virus with tropism for B cells develop into a disease of the central nervous system (CNS)? In MS, there is an inflamma-

## Multiple sclerosis sparked by virus-led autoimmunity

Hartmut Wekerle

---

Understanding factors that lead to the development of multiple sclerosis might aid efforts to develop new therapies. Clinical data now implicate a viral culprit and immune-system dysfunction as underlying factors in this condition.

Most people who study multiple sclerosis (MS) propose that the factors underlying initiation of the disease enter the central nervous system (CNS) from outside the brain. The debate about the nature of these factors has split researchers into two main camps. Most see autoimmunity as the driving factor for the illness, but a minority invoke viral culprits. Writing in *Nature*, Lanz *et al.*<sup>3</sup> report evidence that might settle this debate through a compromise solution.

# Clonally expanded B cells in multiple sclerosis bind EBV EBNA1 and GlialCAM

Multiple sclerosis (MS) is a heterogeneous autoimmune disease in which autoreactive lymphocytes attack the myelin sheath of the central nervous system. B lymphocytes in the cerebrospinal fluid (CSF) of patients with MS contribute to inflammation and secrete oligoclonal immunoglobulins<sup>1,2</sup>. Epstein–Barr virus (EBV) infection has been epidemiologically linked to MS, but its pathological role remains unclear<sup>3</sup>. Here we demonstrate high-affinity molecular mimicry between the EBV transcription factor EBV nuclear antigen 1 (EBNA1) and the central nervous system protein glial cell adhesion molecule (GlialCAM) and provide structural and in vivo functional evidence for its relevance. A cross-reactive CSF-derived antibody was initially identified by single-cell sequencing of the paired-chain B-cell repertoire of MS blood and CSF, followed by protein microarray-based testing of recombinantly expressed CSF-derived antibodies against MS-associated viruses.

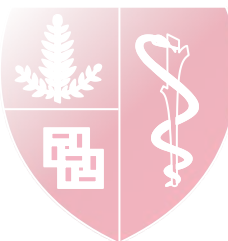

Sequence analysis, affinity measurements and the crystal structure of the EBNA1–peptide epitope in complex with the autoreactive Fab fragment enabled tracking of the development of the naive EBNA1-restricted antibody to a mature EBNA1–GlialCAM cross-reactive antibody. Molecular mimicry is facilitated by a post-translational modification of GlialCAM. EBNA1 immunization exacerbates disease in a mouse model of MS, and anti-EBNA1 and anti-GlialCAM antibodies are prevalent in patients with MS. Our results provide a mechanistic link for the association between MS and EBV and could guide the development of new MS therapies.

## AN ELECTROPHORETIC STUDY OF THE PROTEIN COMPONENTS IN CEREBROSPINAL FLUID AND THEIR RELATION- SHIP TO THE SERUM PROTEINS<sup>1</sup>

BY ELVIN A. KABAT, DAN H. MOORE AND HAROLD LANDOW<sup>2</sup>

*(From the Departments of Neurology and Anatomy and the Electrophoresis Laboratory,  
College of Physicians and Surgeons, Columbia University, and  
the Neurological Institute, New York)*

(Received for publication May 2, 1942)  
SUMMARY

1. The electrophoretic pattern of cerebrospinal fluid resembles that of serum.
2. Alterations in the composition of the protein components of serum are reflected in the cerebrospinal fluid, but the changes are not as marked.

In neurosyphilis, however, an increased gamma globulin occurs in cerebrospinal fluid, without similar changes in the blood stream.

3. Colloidal gold activity is associated with the gamma globulin fraction, and albumin has an inhibiting effect on the colloidal gold reaction.

## Before Electrophoresis

Modern biochemical analysis of human CSF proteins is usually dated back to the discovery of intrathecal synthesis of IgG in 1942 by Elvin Kabat [4]. Before that, the colloidal gold activity method was prevailing for analysis of CSF proteins [5]. The basis for the colloidal gold activity method was that proteins, due to their physicochemi-

cal properties, can serve as either flocculants or stabilizers for gold colloids. It did not allow quantification of the globulin fraction, but depended on the relative proportion of albumin to  $\gamma$ -globulin. The colloidal gold method was invented in 1912 by Carl Lange, an assistant physician at the Rudolf Virchow Hospital in Berlin, as a diagnostic test for neurosyphilis [6]. It was indeed most sensitive in patients with neurosyphilis, but some MS patients also displayed an abnormal protein precipitation pattern of CSF proteins, commonly denoted a paretic Lange curve [7]. Although improved by controlling the pH and the size of the gold particles [8], the sensitivity and specificity of the colloidal gold activity method in MS were low and varied greatly between laboratories [9].

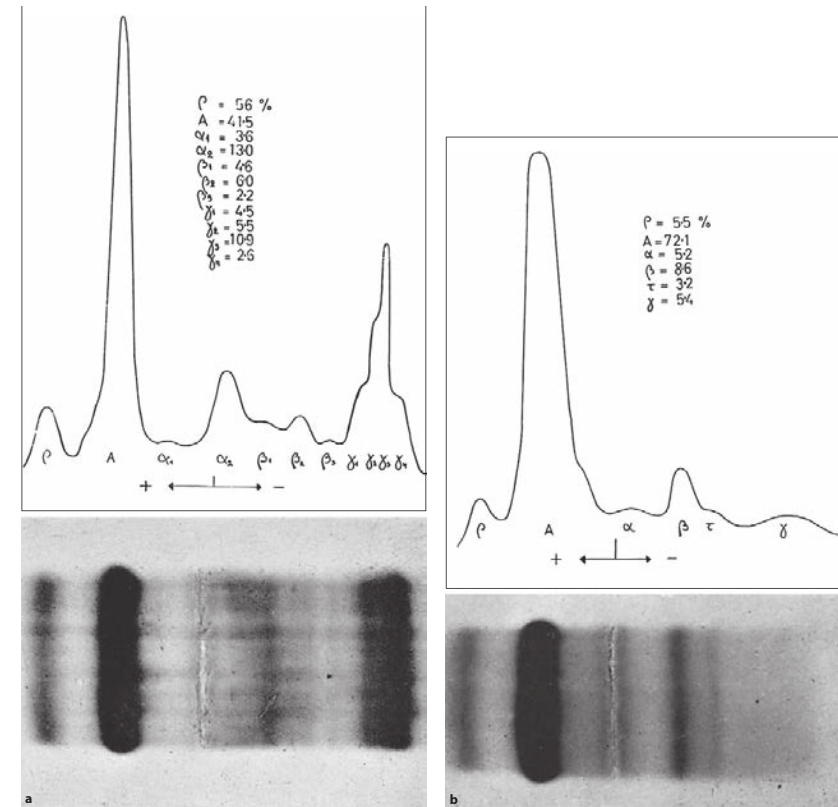

## Detection of Intrathecal Synthesis of IgG

In 1930 the Noble Prize laureate Arne Tiselius published his thesis on moving boundary electrophoresis [10]. By this method, sharp electrophoretic boundaries of ionized molecules could be obtained, and this allowed Tiselius to describe moving boundaries corresponding to albumin,  $\alpha$ -,  $\beta$ - and  $\gamma$ -globulin in serum [11]. The biochemist Elvin Kabat learned moving boundary electrophoresis from Tiselius in Uppsala [11]. Kabat returned to Columbia University in New York in 1941, and in 1942 he used the Tiselius method to demonstrate that colloidal gold activity was associated with the  $\gamma$ -globulin fraction in CSF [1]. The most impressive increase in  $\gamma$ -globulin in CSF was noted in patients with neurosyphilis. One of the five MS patients studied displayed a high concentration of  $\gamma$ -globulin in CSF, but this patient also had a high concentration of  $\gamma$ -globulin in serum. The conclusion that ‘some formation of gamma globulin could take place within the tissues of the central nervous system and be poured into the cerebrospinal fluid’ [1] was therefore based on observations in neurosyphilis and not in MS.

Denise Karcher 1959

separate individual IgG subfractions. In 1959, Denise Karcher reported that agar electrophoresis was superior to paper electrophoresis for separation of  $\gamma$ -globulins in CSF [21]. In this report, individual IgG subfractions were not directly visible by inspection of the agar gel. However, densitometry revealed that the IgG fraction in the CSF from a patient with subacute sclerosing panencephalitis

**Fig. 1.** The first demonstration of different mobilities of  $\gamma$ -globulin subfractions in CSF. **a** Densitometry (upper panel) of agar electrophoresis (lower panel) of concentrated CSF from a patient with subacute sclerosing panencephalitis displays four subfractions of  $\gamma$ -globulin ( $\gamma_1$ -4). **b** Densitometry of agar electrophoresis of normal CSF. Reproduced from Karcher et al. [21] with permission from Wiley.

(which was known as subacute sclerosing leukoencephalitis at that time) was subdivided into 4 subfractions denoted  $\gamma_1$ -4 (fig. 1). This picture is probably as close to the birth of the OCB as we can get, and prompted the conclusion that: 'Electrophoresis in agar gel reveals in the CSF

of subacute sclerosing leukoencephalitis patients an increase in the  $\gamma$ -globulins, which can be subdivided into several individual fractions. These subfractions which differ in mobility may probably also differ in chemical composition' [21].

### Intrathecal Synthesis of OCB

Lowenthal, van Sande and Karcher did not include serum samples in their initial reports [21, 22], and it was therefore not possible to tell whether the IgG fractions appearing as OCB were produced intrathecally or elsewhere. The importance of comparing the patterns of OCB in CSF and serum in order to obtain qualitative evidence of intrathecal synthesis of IgG was particularly underscored by Laterre, who also showed that the  $\gamma$ -globulin fraction of normal CSF was composed of both IgG and of tissue-like proteins [28]. Hans Link demonstrated that OCB could be detected in CSF from patients who did not display quantitative evidence for intrathecal synthesis of IgG [29, 30]. In a study of 2,043 patients, Laterre indeed demonstrated that intrathecally synthesized OCB were detectable with agar electrophoresis in 86.9% of patients with definite MS, and that this assay was more sensitive than quantitative assays in detecting intrathecal IgG synthesis [31].

White blood cell migration across a blood vessel, 1918. [Cajal Institute / CSIC / Madrid]

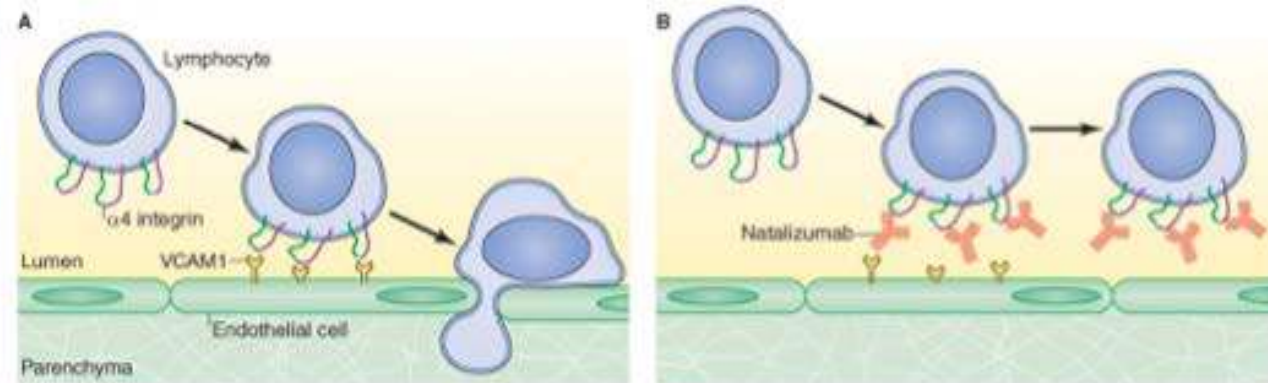

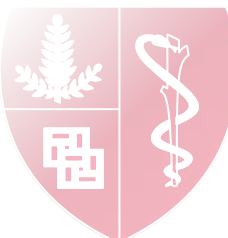

Figure 1. Natalizumab blocks lymphocyte homing in MS. (A)  $\alpha 4$  integrin binds to vascular cell adhesion molecule 1 (VCAM1) and to osteopontin (not depicted) on inflamed brain endothelium. This interaction gives lymphocytes access to the central nervous system (CNS). The presence of immune cells in the brain is a prominent feature of MS. (B) Natalizumab, a humanized antibody to  $\alpha 4$  integrin, blocks binding of lymphocytes to VCAM and osteopontin on inflamed brain endothelium, thereby preventing lymphocyte entry into the CNS.

## The discovery of natalizumab, a potent therapeutic for multiple sclerosis

Lawrence Steinman

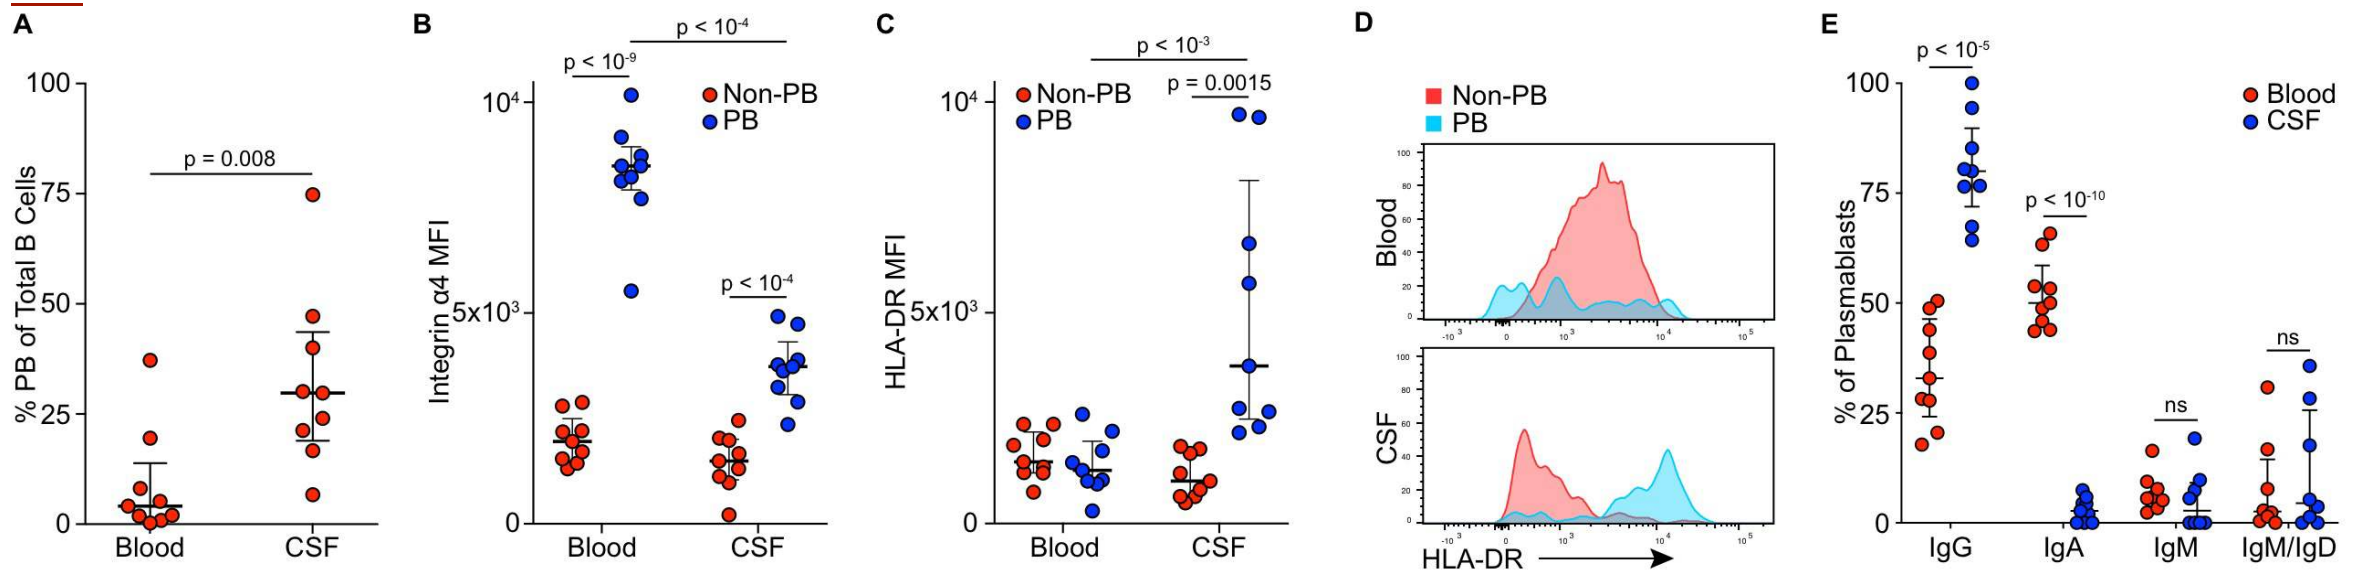

Multiple sclerosis (MS) is the major inflammatory demyelinating disease of the central nervous system. There is strong evidence that an immune response in the brain is a critical component of the disease. In 1992, in a collaboration between academia and biotechnology, my colleagues and I showed that  $\alpha 4$  integrin was the critical molecule involved in the homing of immune cells into the inflamed brain. Was it sheer luck that these results led to the development of a drug for MS?

# Plasmablasts Enriched in CSF of MS Patients Express $\alpha 4$ integrin

We probed mAb MS39p2w174 on a HuProt protein microarray, which represents >16,000 proteins spanning >80% of the human proteome

# Affinity Maturation from Germline is Necessary for High Affinity Binding to GlialCAM

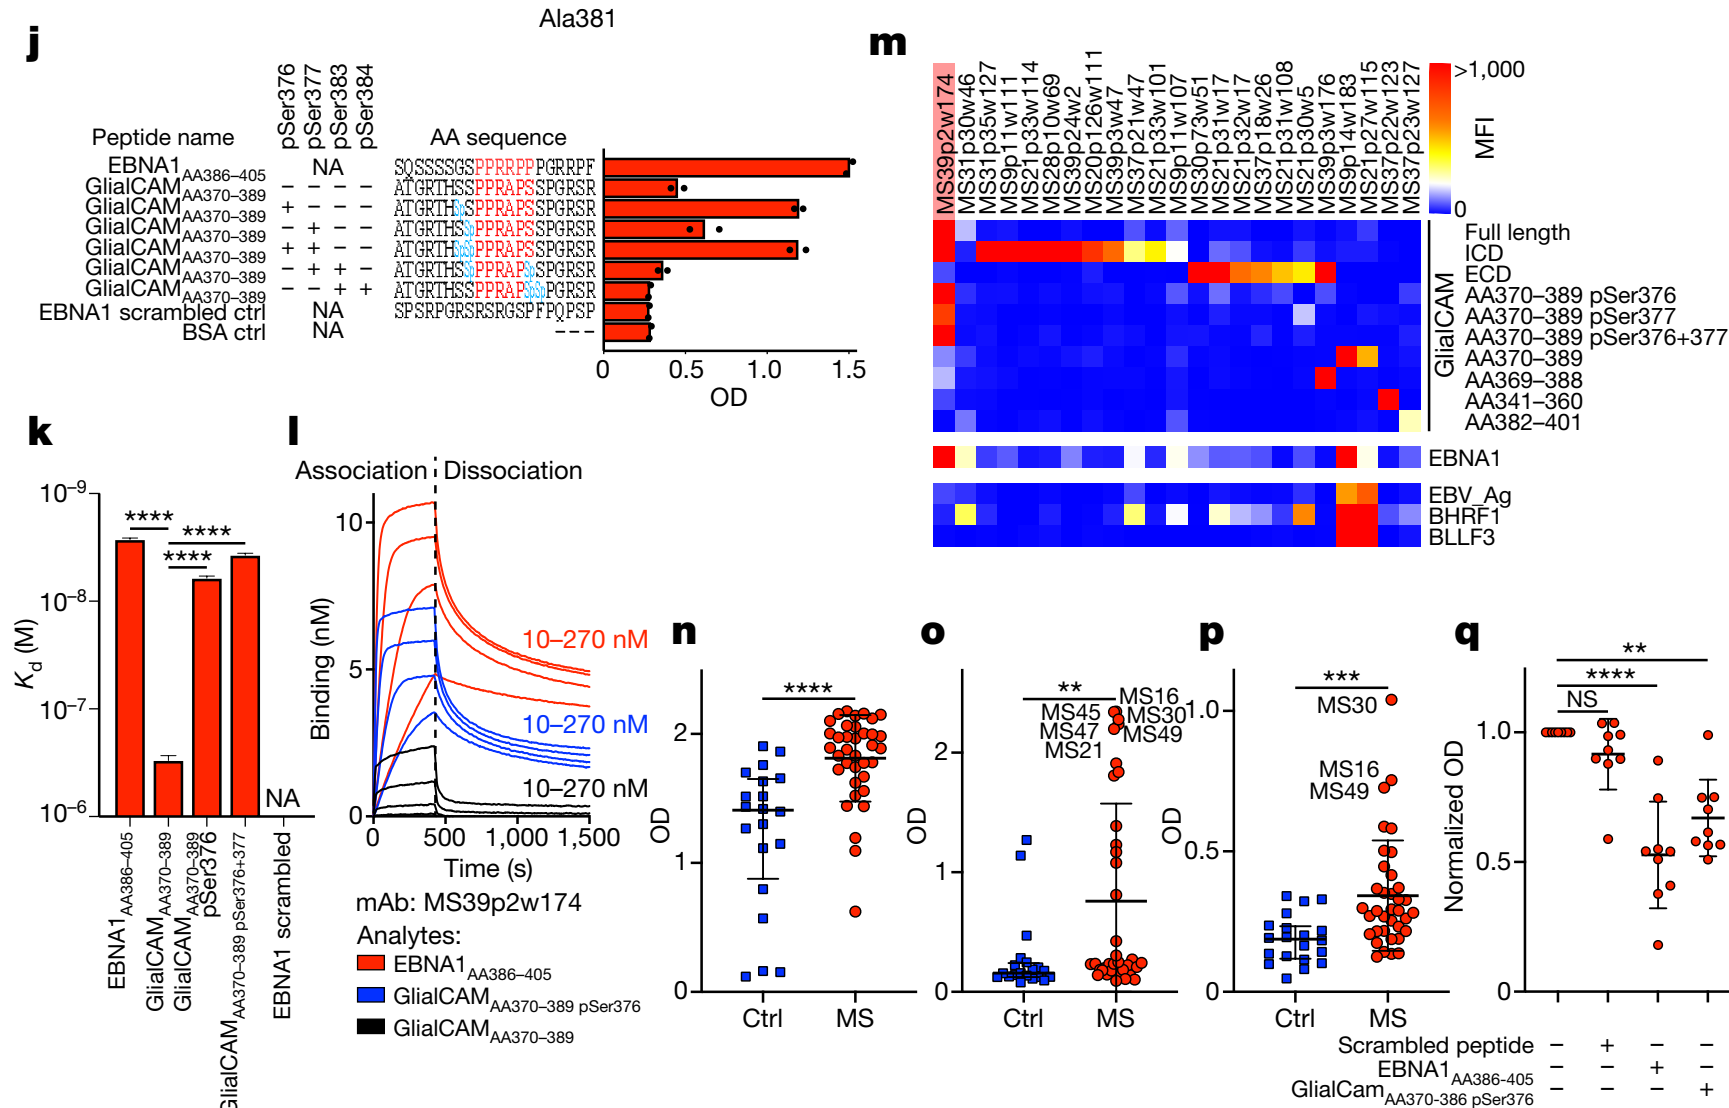

Nearly everyone is infected with EBV, but only a small fraction develop MS. Thus, other factors, such as genetic susceptibility, are important in MS pathogenesis. Certain genes, such as those encoding the antigen-presenting human leukocyte antigen (HLA) proteins, determine the portion of a protein that is presented to the immune system. **Other genes control modifications in EBV-associated proteins, including phosphorylation. Such genes are critical for modulating molecular mimicry (4, 11).** Thus, given these additional gating factors in MS pathogenesis, **infection with EBV is likely to be necessary, but not sufficient**, to trigger development of MS. Infection with EBV is the initial pathogenic step in MS, but additional fuses must be ignited for the full pathophysiology

The ability to control autoreactive T cells without inducing systemic immune suppression is the major goal for treatment of autoimmune diseases. The key challenge is the safe and efficient delivery of pharmaceutically well-defined antigens in a noninflammatory context. Here, we show that systemic delivery of nanoparticle-formulated 1 methylpseudouridine-modified messenger RNA (m1Ψ mRNA) coding for disease-related autoantigens results in antigen presentation on splenic CD11c<sup>+</sup> antigen-presenting cells in the absence of costimulatory signals. In several mouse models of multiple sclerosis, the disease is suppressed by treatment with such m1Ψ mRNA. The treatment effect is associated with a reduction of effector T cells and the development of regulatory T cell (T<sub>reg</sub> cell) populations. Notably, these T<sub>reg</sub> cells execute strong bystander immunosuppression and thus improve disease induced by cognate and noncognate autoantigens.

The diversity of autoimmune responses poses a formidable challenge to the development of antigen-specific tolerizing therapy. We developed 'myelin proteome' microarrays to profile the evolution of autoantibody responses in experimental autoimmune encephalomyelitis (EAE), a model for multiple sclerosis (MS). Increased diversity of autoantibody responses in acute EAE predicted a more severe clinical course. Chronic EAE was associated with previously undescribed extensive intra- and intermolecular epitope spreading of autoreactive B-cell responses. Array analysis of autoantigens targeted in acute EAE was used to guide the choice of autoantigen cDNAs to be incorporated into expression plasmids so as to generate tolerizing vaccines. Tolerizing DNA vaccines encoding a greater number of array-determined myelin targets proved superior in treating established EAE and reduced epitope spreading of autoreactive B-cell responses. Proteomic monitoring of autoantibody responses provides a useful approach to monitor autoimmune disease and to develop and tailor disease- and patient-specific tolerizing DNA vaccines.

---

**Objective:** To evaluate the efficacy and safety of BHT-3009 in relapsing-remitting multiple sclerosis (MS) and to confirm that BHT-3009 causes immune tolerance.

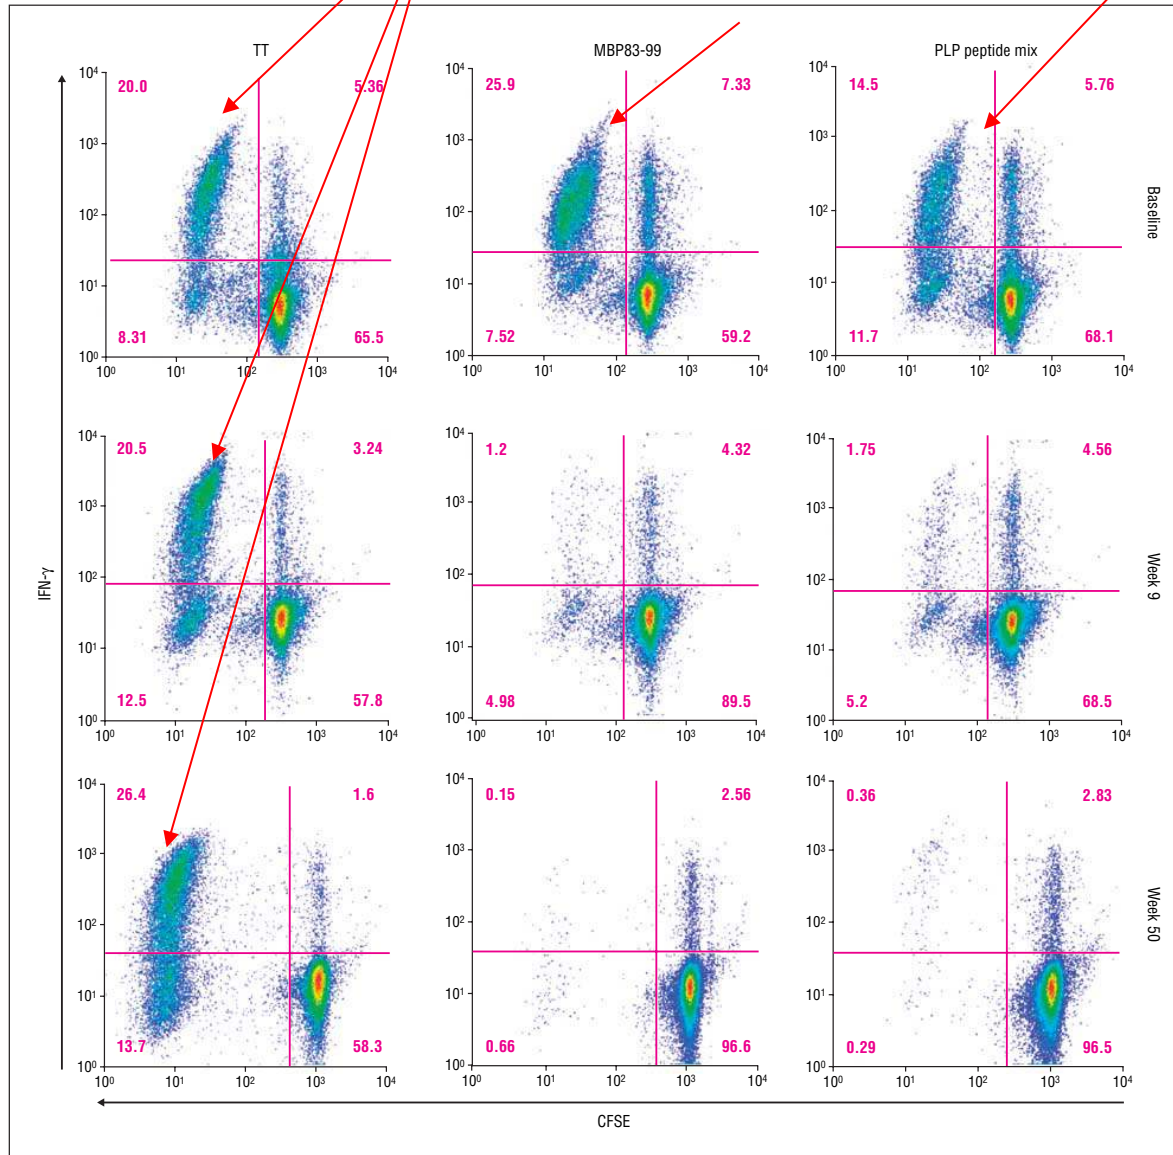

**Methods:** BHT-3009 is a tolerizing DNA vaccine for MS, encoding full-length human myelin basic protein. Relapsing-remitting MS patients were randomized 1:1:1 into three groups: placebo, 0.5mg BHT-3009, or 1.5mg BHT-3009, given intramuscularly at weeks 0, 2, 4, and every 4 weeks thereafter until week 44. The primary end point was the 4-week rate of occurrence of new gadolinium-enhancing lesions on brain magnetic resonance images from weeks 28 to 48. Protein microarrays were used to measure levels of anti-myelin autoantibodies.

**Results:** Compared with placebo, in the 267 patient analysis population the median 4-week rate of new enhancing lesions during weeks 28 to 48 was 50% lower with 0.5mg BHT-3009 ( $p = 0.07$ ) and during weeks 8 to 48 was 61% lower with 0.5mg BHT-3009 ( $p = 0.05$ ). The mean volume of enhancing lesions at week 48 was 51% lower on 0.5mg BHT-3009 compared with placebo ( $p = 0.02$ ). No significant improvement in magnetic resonance imaging lesion parameters was observed with 1.5mg BHT-3009. Dramatic reductions in 23 myelin-specific autoantibodies in the 0.5mg BHT-3009 arm were observed, but not with placebo or 1.5mg BHT-3009.

**Conclusions:** In relapsing-remitting MS patients, treatment with the lower dose (0.5mg) of BHT-3009 for 44 weeks nearly attained the primary end point for reduction of the rate of new enhancing magnetic resonance imaging lesions ( $p = 0.07$ ) and achieved several secondary end points including a reduction of the rate of enhancing magnetic resonance imaging lesions from weeks 8 to 48 ( $p = 0.05$ ). Immunological data in a preselected subgroup of patients also indicated that treatment with 0.5mg induced antigen-specific immune tolerance. The greater dose was ineffective.

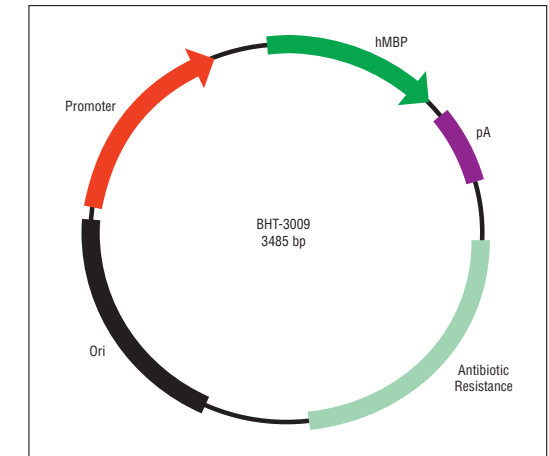

# Reduced IFN- $\gamma$ Response in MBP T cells, with some effect on PLP T cells, but not Tet Tox T cells

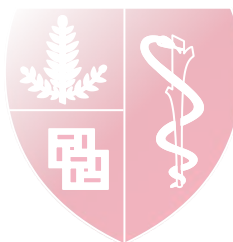

5 of 5 patients with *decreased* MBP T cell response

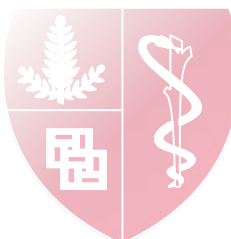

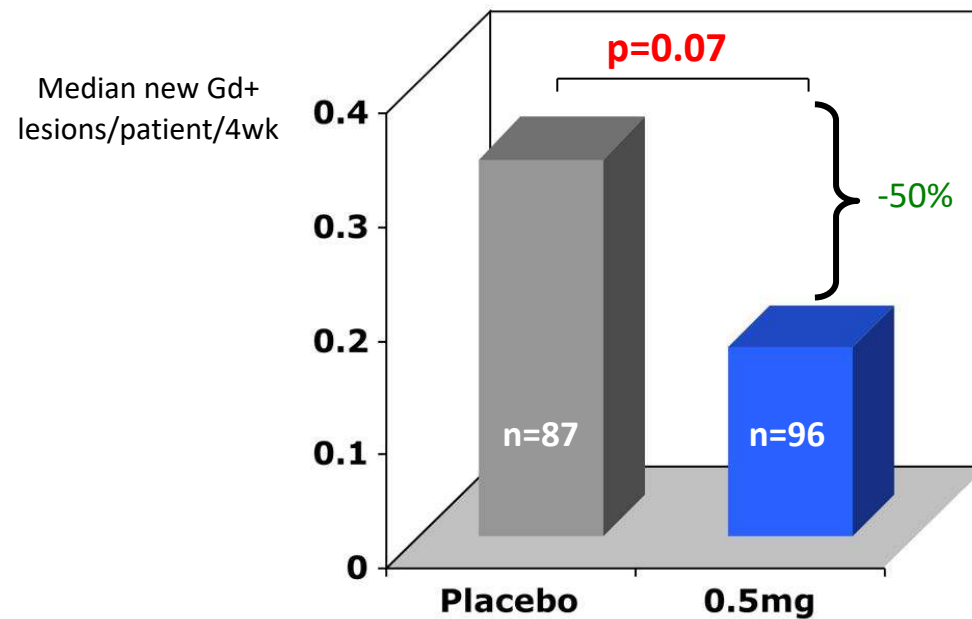

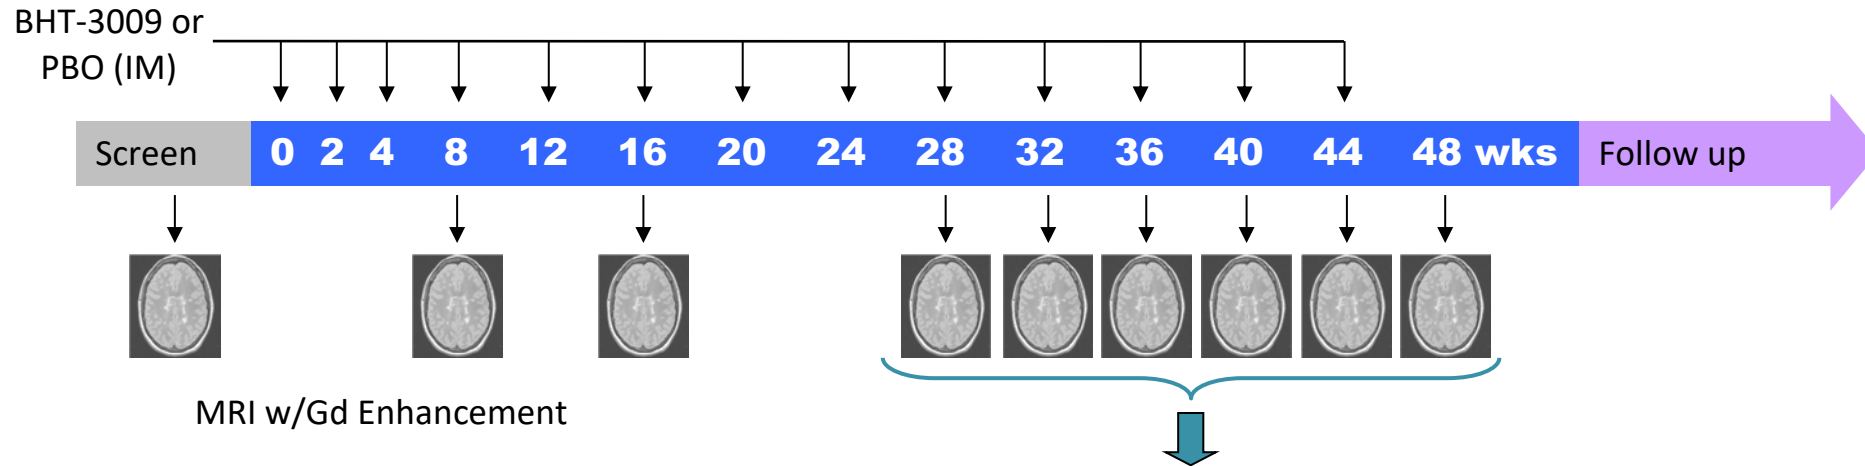

1 patient negative at baseline, and remained negative after treatment

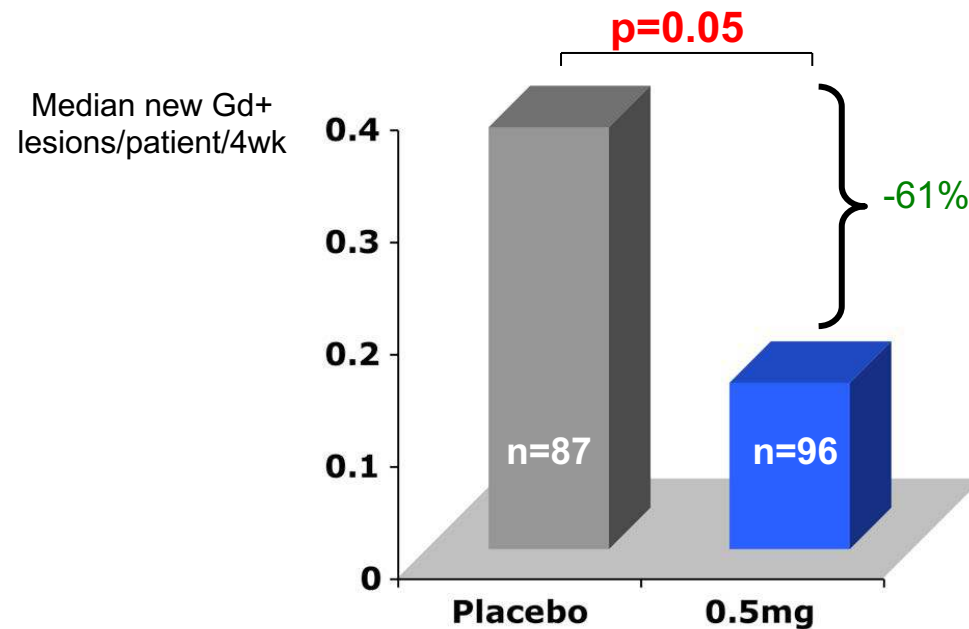

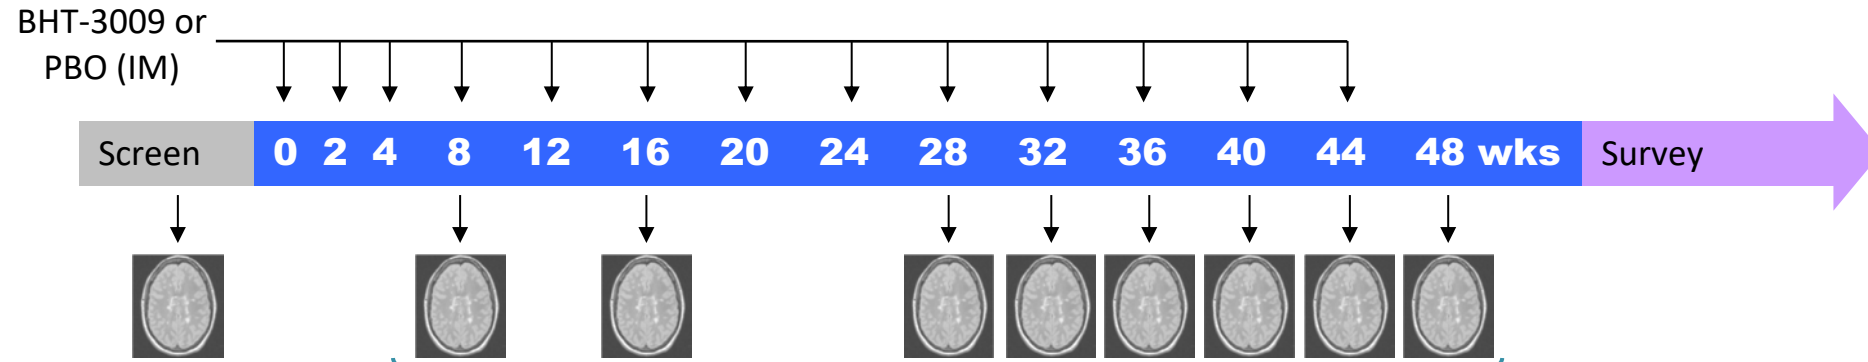

We isolated the full-length complementary DNA encoding the 18.5-kDa isoform of human MBP from a human brain complementary DNA library. This was cloned into a modified expression plasmid driven by a eukaryotic promoter. The expression plasmid was created as a derivative of the pVAX1 plasmid, where **certain immunostimulatory CpG motifs were removed and immuno- inhibitory GpG motifs were included**. We have previously shown that oligonucleotides containing these GpG motifs either alone or combined with DNA vaccine plas- mids were effective in treating animal models of several prototypic autoimmune diseases

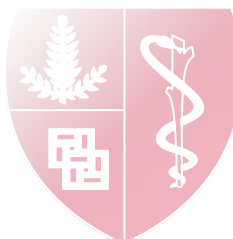

## Gadolinium-Enhancing (Gd+) Lesions

## Phase II: Gadolinium-Enhancing (Gd+) Lesions

PP population

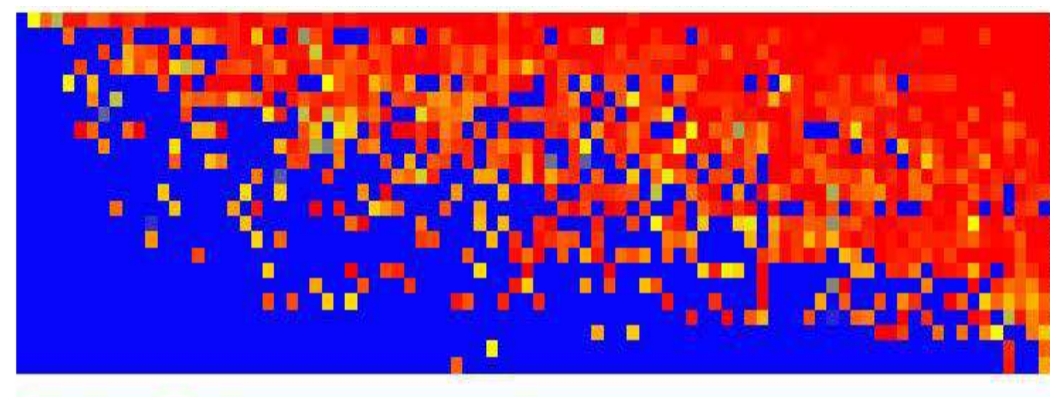

Patients with Highest MBP Antibody in CSF had Best Response, leading to a conjecture:

**Conjecture: Tolerization works best when autoreactivity is highest.**

**Why capturing the cells to tolerize makes sense.**
